Retreatment of a Resected Tooth Associated with a Large Periradicular Lesion by Using a Triple Antibiotic Paste and Mineral Trioxide Aggregate: A Case Report with a Thirty-month Follow-up

Adem Kusgoz, DDS, PhD,* Tabsin Yildirim, DDS, PhD,† Kursat Er, DDS, PhD,‡ and Ipek Arslan*  

Abstract

Introduction: Trauma to the teeth and supporting structures is a frequent problem among children. Endodontic treatment is necessary for 41.3% of traumatized teeth. Two of the most important criteria for successful endodontic treatment are the elimination of microorganisms and apical sealing. A combination of antibiotic drugs (metranidazole, ciprofloxacin, and minocycline) is used to eliminate target bacteria, which are possible sources of endodontic lesions. For cases in which apical sealing is difficult, specific materials to plug the apical region have been advocated. Mineral trioxide aggregate (MTA) has become the material of choice because it is biocompatible and has bacteriostatic action. Methods: This case report describes the nonsurgical retreatment of a traumatized tooth that had already undergone unsuccessful apical resection associated with a large periradicular lesion. A combination of antibiotic drugs was used as an intracanal medicament, and MTA was used to obtain a hermetic seal of the lateral tooth that had undergone unsuccessful apical resection. Results: On follow up, the tooth was clinically and radiographically asymptomatic for 30 months. Conclusions: The results of this case show that MTA and triple antibiotic paste can be used clinically in the treatment of an unsuccessfully resected tooth associated with a large periradicular lesion. (J Endod 2009;35:1603–1606)

Key Words
Large periradicular lesion, MTA, retreatment, triple antibiotic paste

Case Report

A 12-year-old boy was referred to the Department of Pediatric Dentistry in the Dental Faculty of Karadeniz Technical University because of a swelling in his left mandibular region. His medical status was noncontributory. According to his questionnaire, 3 years earlier he had fallen off his bicycle and broken his mandibular left lateral tooth. At that time, a root canal treatment and apical resection were performed on this tooth at another clinic. Two years later, the symptoms returned.

In the intraoral examination, an intraoral fistula was located in the mandibular left lateral region; in radiographic examination, panoramic and periapical radiographs were analyzed. A large radiolucent lesion with a well-defined margin around the mandibular left lateral tooth’s radicular region was seen (Figs. 1A and 2A). The electronic pulp test on the mandibular left canine was negative. After evaluating all the data, a root canal retreatment of the left mandibular lateral tooth and left mandibular canine tooth was planned. A rubber dam was applied, and the access cavities were prepared. The root canal filling material was removed by using Gates-Glidden and K-files. The drainage of pus was noted. This procedure was repeated until no gutta-percha, sealer,
or pus was present on the files and paper points. After ensuring the presence of a clean root canal wall, radiography was performed. The working lengths of the tooth canals were measured by inserting a #60 file for the lateral tooth and #10 file for the canine tooth (K-file; Maillefer, Ballaigues, Switzerland), and radiography was taken. The teeth were instrumented to ISO size 100 for the lateral and 35 for the canine tooth by using the step-back technique. During instrumentation, the canals were irrigated with 2.5% sodium hypochlorite by using 27-gauge endodontic needles after each instrument. The canals were dried with sterile paper points and then dressed with calcium hydroxide (Sultan, Englewood, NJ). Sterile cotton pellets were inserted into the access cavities before sealing them with temporary filling material. The calcium hydroxide dressing was changed every 2 weeks for a total of 3 times. Because the symptoms were not eliminated, the treatment procedure was changed. A triple antibiotic paste was selected for the intracanal dressing. A mixture of ciprofloxacin (Ciflosin; Deva, Istanbul, Turkey), metronidazole (Flagyl; Eczacibasi, Istanbul, Turkey), and minocycline (M9511; Sigma-Aldrich, St Louis, MO) paste (0.5 mg of each), as described by Takushige et al (7), was prepared. The mixture had a creamy consistency and was spun down the root canal with a lentulo spiral. It was changed every month for a period of 3 months until the teeth displayed no symptoms. On examination, the teeth showed no sensitivity to percussion, and the soft tissues were healthy. According to these data, the decision was made to fill the canals. The teeth were reopened, and the antibiotic paste was removed. The canals were irrigated with 2.5% sodium hypochlorite. After that, the root canal of the canine tooth was obturated with gutta-percha (Diadent; Diadent Group International, Chongchong, Korea) and AH 26 (Dentsply, Konstanz, Germany) by using a lateral condensation technique. The apical part of the root canal of the lateral tooth was obturated with gray MTA (Dentsply-Maillefer, Ballaigues, Switzerland). MTA was prepared according to the manufacturer’s instructions. An endodontic plunger adequate for the length of the canal was used, and the stopper was fixed 1 mm behind the working length. MTA was inserted into the canal with a mesling gun (Dentsply-Maillefer, Ballaigues, Switzerland) and pushed further in with a plunger. A radiograph was taken to ensure there was no excess. A cotton pellet moistened with distilled water was placed over the MTA, and the access cavity was sealed with a temporary filling. After 24 hours, the temporary filling material and cotton pellet were removed. Then the MTA in the remaining pulp space was obturated with gutta-percha and AH 26 by using a lateral condensation technique (Fig. 1B). The restoration of these teeth was accomplished with composite resin (Z250; 3 M ESPE, St Paul, MN). After 1 year, the radiograph showed complete healing (Fig. 1C, D). After 30 months, the radiograph showed no pathology (Figs. 1E and 2B).

Discussion

Children frequently experience trauma to their teeth and supporting structures (1). Pulp therapy is necessary for 41.3% of traumatized...
canals. The root-end anatomy of resected teeth is similar to that of teeth with open apices, so it is very difficult to obtain a hermetic seal with conventional gutta-percha obturation techniques. Many studies recommended the use of MTA in teeth with necrotic pulps and open apices. Additional studies were performed that were associated with the application of open apices, and it was concluded that MTA can be successfully used in these teeth.

We believe that because of the difficulty in achieving an apical stop, MTA should be used in resected teeth, and consequently, MTA was selected for this case. This is the first known case report in which MTA was used clinically as an apical plug technique for the treatment of unsuccessfully resected teeth, and the patient was followed for 30 months.

Conclusions

As in all dental applications, the diagnosis and treatment plan play a significant role in the successful treatment of traumatic injuries. Therefore, being aware of medical advances and treatment choices is crucial. A triple antibiotic paste can be an alternative material to calcium hydroxide in teeth with a large periradicular lesion when calcium hydroxide has failed. The use of MTA in the treatment of a resected tooth and large periapical lesion is not a routine application; however, MTA positively affected the healing of this tooth during a period of 30 months. In conclusion, MTA and triple antibiotic paste can be used clinically in the treatment of unsuccessfully resected teeth with a large periradicular lesion.
